# An Intro to Network Crypto

Jim Binkley- [jrb@cs.pdx.edu](mailto:jrb@cs.pdx.edu)

# Crypto outline

---

- ◆ overview
- ◆ symmetric crypto (DES ... encryption)
- ◆ hash/MAC/message digest algorithms
- ◆ asymmetric crypto (public key technology)
- ◆ DH - how to start a secure connection
- ◆ KDC - a little bit on shared secret servers
- ◆ signatures - authentication with asymmetric keys
- ◆ certificates - signed public keys
- ◆ a little bit on authentication

# overview

---

- ◆ there are MANY crypto algorithms and MANY academic network secure protocols
- ◆ how they are used in network protocols is another matter
- ◆ traditional IETF RFC said under security considerations (at end of doc)
  - “not considered here” (another F. Flub)
- ◆ new IETF POV: **must consider here**

# symmetric encryption

---

- ◆ both sides know OUT OF BAND shared secret (password, bit string)
- ◆  $\text{encrypt}(\text{key}, \text{plaintext}) \rightarrow \text{cybercrud}(\text{encrypted})$
- ◆  $\text{decrypt}(\text{key}, \text{cybercrud}) \rightarrow \text{plaintext}$
- ◆ encode/decode use same key (symmetric)
  - shared secret on both sides
- ◆ algorithms include: DES, 3DES, IDEA(128), BLOWFISH, SKIPJACK, new AES
- ◆ ssh uses 128 bit keyed IDEA
- ◆ DES key 56 bits - 0xdeadbeefdeadbeef

# DES-CBC

---

- ◆ Cipher Block Chaining Mode
- ◆ DES processes one 64 bit block of data at a time (key is 64 bits (8 bits not important))
- ◆ CBC is used so that e.g., two 64 bit blocks in a row that are the same, do NOT produce two 64 encrypted blocks that are the same
- ◆  $C(n) = E_k [C(n-1) \text{ xor Plaintext}(n)]$
- ◆ requires known IV or initialization vector

# pros/cons

---

- ◆ pros

- faster than asymmetric

- ◆ cons

- shared secrets do not scale in general to many users
  - » more people know secret, less of a secret
- secrets hard to distribute
- export laws have blocked encryption software
- DES key length too short?! (RSA challenge)
  - » 2-3 bits a year used up by Moore's law

# mention briefcase man Jim

---

- ◆ how do get the shared secret from spot A to B
- ◆ no we do not publish it on the web
- ◆ “out of band”
- ◆ this is a GENERAL problem in secret distribution
  - is is  $N^2$  for symmetric keys, but can be made linear with a server Or with public-key crypto and a server
- ◆ in general the need for briefcase man is always there else you are susceptible to a MITM attack

# challenge-response with DES

---

- ◆ assume client/server & shared secret

client:

server:

----- send ID (bob) -->

<----- send random challenge X

compute  $E = f(X, \text{DES key})$

----- send E to server -->

decode(E, key)

== X

- ◆ authentication mechanism (shared secret)

# cryptanalysis means what?

---

- ◆ decoding the cybercrud or finding weaknesses in algorithms
- ◆ hardest if you don't know any plaintext
- ◆ easier if you know some: known plaintext attack
- ◆ easiest if you can suggest the plaintext: proposed plaintext attack
- ◆ point: end-end crypto is more secure, why?

# why so?

---

e.g., we have crypto (like IPSEC) between a host and a border router, but not to the server.

Bart the evil one can inject data to host A and see how it is encrypted. ...

# media digest algorithms aka

---

- ◆ hash functions OR
- ◆ one-way functions OR
- ◆ message authentication codes (if used with a shared-secret key)
- ◆ e.g., MD5, SHA, HMAC-MD5, HMAC-SHA
- ◆ MD5 - RFC 1321 (Ron Rivest)
- ◆ Secure Hash Alg. - NIST, FIPS PUB 180-1

# media digest functions

---

- ◆ take a message, and produce a non-reproducible bit string ( hash or media digest for a file)
  - MD(msg) -> bit string (128 bits with MD5)
- ◆ MD(msg, shared secret)-> authenticator
- ◆ may be used for password mechanisms
  - longer strings better, FreeBSD 128 byte passwd length
- ◆ used with signatures for efficiency reasons
  - MD algorithm faster than public-key
  - we hash the msg, then sign it

# examples of MD functions

---

- ◆ download X and MD
  - compare X to MD to make sure you didn't have bit rot
  - does this prevent a hacker from changing X?
- ◆ virus game1.exe upload to cwsandbox
  - get media digest - may determine they have seen it before
- ◆ nasty porno file has MD
  - police agencies have database of MDs
- ◆ used in ID system like tripwire
  - file X hasn't changed recently

# when we talk about signatures?

---

- ◆ we are vague ...
- ◆ 1. pattern matching algorithm used to id virus bits in a file or bits on network
  - what are counter-measures on the black side?
- ◆ 2. MD signature used to type files
- ◆ 3. digital signature - public key crypto used to sign document (actually sign MD)

# one time pad with MD algorithm

---

- ◆ a one-time pad is in theory:
  - an inexhaustible set of random bits of which there are 2 copies
  - briefcase man has gotten it from Alice to Bob
  - we take the msg of N bits and take the next N bits from our inexhaustible store and xor them together to encrypt
  - xor again to decrypt
- ◆ or we might use it just for secret key generation
  - every time we need a key, we take a phrase from a shared book and hash it with MD5 to make some bits

## how about like this?

---

- ◆ Alice and Bob have a shared secret  $K(ab)$
- ◆ Alice computes  $MD(Kab)$
- ◆ she xors the message with the hash,
- ◆ for the next message block she does
- ◆  $MD(MD(Kab))$
- ◆ Alice needs an IV too, but never mind
- ◆ we also need a message integrity check

# examples

---

- ◆ MD5 - media digest 5, 128 bit string (key)
  - used with RSA signatures
- ◆ SHA - 160 bits,
  - used with DSS public key crypto scheme
- ◆ MD5 has “flaws” - we may need better MD algorithms or different ideas
- ◆ whirlpool - new hash (512 bit digest)

# ssdeep - different take on MD algorithm

---

- ◆ fuzzy hashing - Jesse Kornblum
- ◆ basic idea: hash can show that f1 and f2 are similar (or totally different)
- ◆ ssdeep is a tool he developed
- ◆ shadowserver has used it to show similarities in various malwares produced by RBN

# HMAC - MD5 (or SHA)

---

- ◆ felt that MD5 and its like needed to be made more secure with attention to MAC function, not media digest function
- ◆ also of course, no export control ...
- ◆ HMAC - hash message auth. code, RFC2104
- ◆ roughly:  $f[(K \text{ xor } C1) || f[K \text{ xor } C2] || \text{msg}]$ 
  - essentially two rounds of mac function (f) with cybercrud worked in as appropriate

# an example - Mobile-IP

---

Home Agent

Mobile-IP authenticated UDP packet

registration reply

registration  
request

Mobile Node

# Mobile-IP

---

- ◆ Home Agent keeps key-list of (mobile node IP addresses, per MN 128bit MD5 key)
- ◆ MN and HA share 128 bit MD5 shared secret
- ◆ compute  $f(\text{key}, \text{msg})$  and store hash in Mobile-IP registration message
- ◆ routing not setup if authentication fails
- ◆ note authentication is per IP address as ID

# Mobile-IP auth. header encapsulation

---

authenticated part

mobile-ip message part (app layer) includes both

1. time bits (nonce)
2. MN/HA ip addresses (ids)

# Diffie-Hellman algorithm

---

- ◆ guess who invented it
- ◆ public key but doesn't do signatures/encryption
- ◆ allows two entities that share two public numbers to arrive at a shared secret that can be used for encryption of further messages
- ◆ basis of many “session key” algorithms
- ◆ share secure channel and periodically change key (use DH to start, DES for bulk work)

# DH might go like this

---

- ◆ Alice/Bob a priori agree on two public numbers:
  - $p$ , a large ( $\geq 512$  bits) prime
  - $g$ , where  $g < p$
- ◆ pre-compute:

– Alice	Bob	comment
– $S(a) = f(\text{random})$	$S(b) = f(\text{random})$	512 bits
– $T(a) = g^{**}S(a) \bmod p$	$T(b) = g^{**}S(b) \bmod p$	
- ◆ Alice sends  $T(a)$  to Bob; Bob sends  $T(b)$  to Alice

## cont:

---

- ◆ post-compute of shared secret key material
  - Alice                      Bob
  - $S(\text{secret}) = T(b) ** S(a) \text{ mod } p$   
 $S(\text{secret}) = T(a) ** S(b) \text{ mod } p$
- ◆  $S(\text{secret})$  is the shared secret key usable for encryption/authentication and is the same because
- ◆  $T(b)**S(a) = T(a) ** S(b)$  as
- ◆  $T(b) ** S(a) = (g ** S(b))** S(a) = (g **S(a)) ** S(b) = T(a) ** S(b)$

## cont:

---

- ◆ hard to compute  $S(a)$  given only  $T(a)$ ,  $g$ ,  $p$  (hard to compute discrete log)
- ◆ may periodically recompute  $S(\text{secret})$  based on use of key
  - used for time  $T$  then recompute
  - used for data amount Bytes then recompute

# questions re DH

---

- ◆ is unauthenticated DH subject to any active attacks?
  - if so, how?
- ◆ how can said attacks be fixed with what you know so far?
- ◆ why can't Black Bart intercept Alice's first packet and passively compute the shared secret?

# paradigm for secure algorithm

---

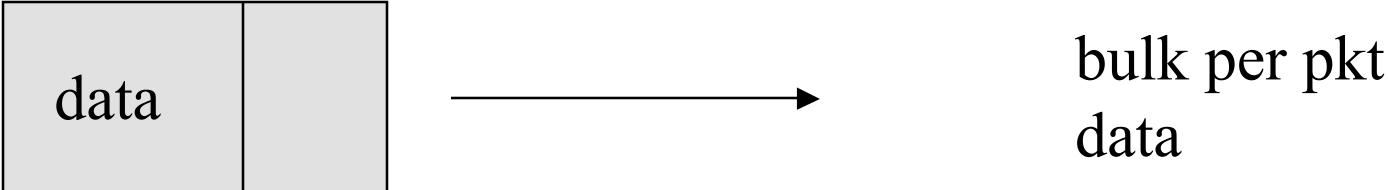

- ◆ use asymmetric crypto to secure DH messages (e.g., RSA) or even HMAC-MD5
- ◆ use DH and handshake to setup session keys and agreement on which crypto algorithms to use for encryption/authentication
- ◆ send bulk messages with session-key derived encrypted or authenticated packets
  - using MD5/DES, SHA/IDEA, whatever

# secure protocol paradigm then:

---

1.  handshake  
DH(authenticated) gives shared secrets

2.  handshake  
let's use encryption X, auth. Y  
(e.g., idea/HMAC-SHA)

3.  bulk per pkt  
data

encrypted/authenticated data (with security header)

# Perfect Forward Secrecy

---

- ◆ PFS defined as:
  - 1. attacker can record entire crypto session
  - 2. attacker can break in and steal keys (public or private)
  - 3. attacker still can't figure out the next session
- ◆ would Alice encrypting Bob's email with Bob's public key have this feature?

# DH with PFS

---

- ◆ Alice sends Bob: [Alice,  $g(a) \bmod p$ ] Alice (sig)
- ◆ Bob sends Alice: [Bob,  $g(b) \bmod p$ ] Bob
- ◆ Alice sends  $\text{hash}(g(ab) \bmod p)$
- ◆ Bob sends  $\text{hash}(1, g(ab) \bmod p)$
- ◆ Both know the hash, and because
  - 1. DH gives private material based on initial random #
  - 2. hash is 1-way
  - we have unknowable secrets

# key-escrow “foilage”

---

- ◆ is something a PFS protocol gives us
- ◆ doesn't matter if big-brother knows all your keys, public/private
- ◆ protocol is unbreakable

# consider this protocol

---

- ◆ generate key via shared-secret and hash
  - and what other properties?
- ◆ both sides do  $\text{sha}(\text{shared-secret}, \text{other?})$
- ◆ use that hash as key for privacy
- ◆ periodically hash the hash at a certain time
  - time past or bytes sent
- ◆ does this give us PFS? if not, what can we do to fix it?

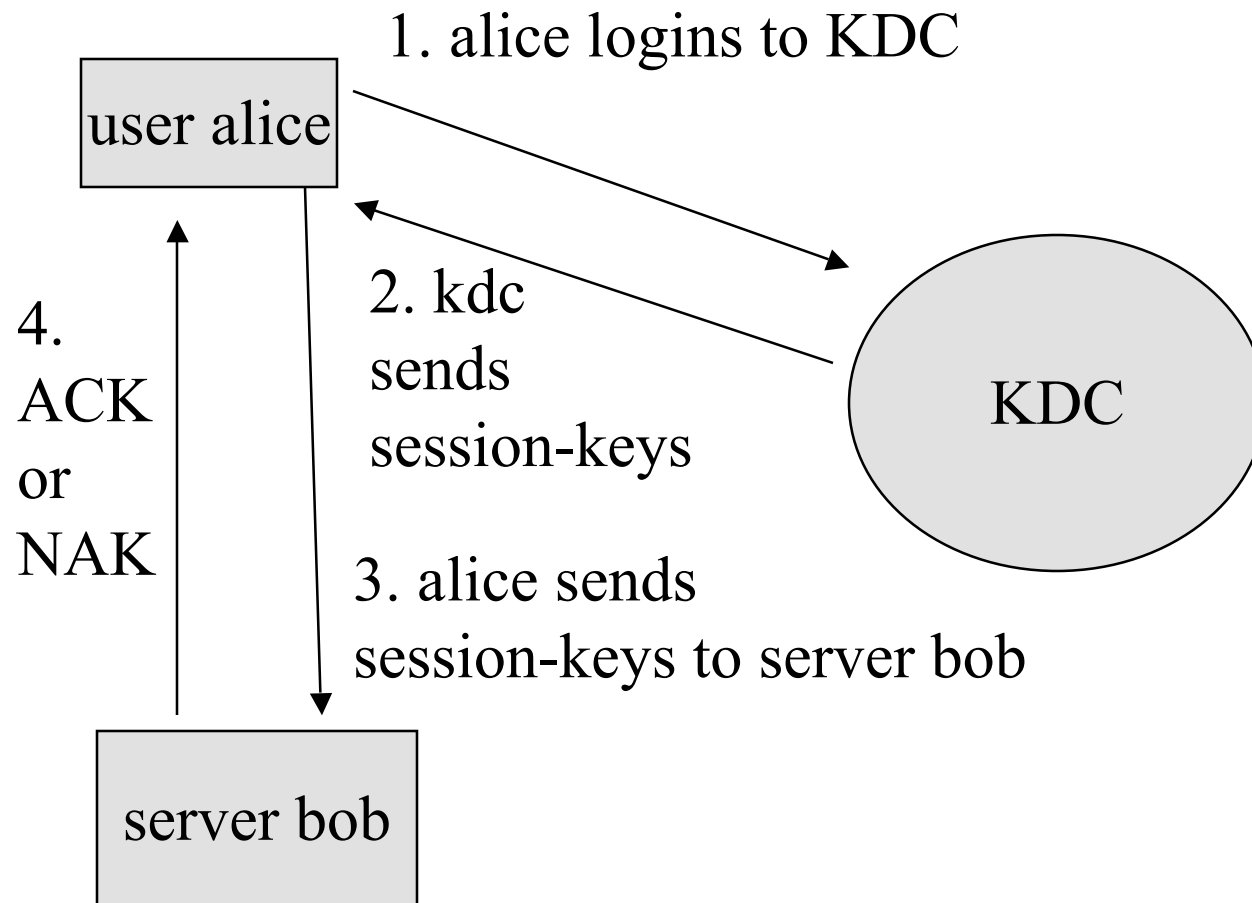

# KDC idea

---

- ◆ DH is one-way to establish shared “session keys”
- ◆ This is also about the idea of using a protocol to establish keys on both sides
- ◆ another old idea is the idea of a symmetric key-server
- ◆ you use a key-exchange protocol to get new keys from it
- ◆ KDC - key distribution center
  - traditional idea: exchange of symmetric keys
  - for indirect authentication

# KDC picture

---

# algorithm underpinnings

---

- ◆ 1. a-priori shared secret between KDC and Alice/Bob
  - 2 master keys
- ◆ 2. Alice gets from KDC two session keys
  - 1. one encrypted for Alice with Alice's master
  - 2. one encrypted for Bob with Bob's master
  - 3. this is a new Alice/Bob session key
- ◆ 3. Alice send's Bob Bob's key, and Bob decrypts with Bob's master key

# symmetric session-key system

---

- ◆ think of the new session keys as a 2-way base secret between Bob and Alice
- ◆ this can be used for an authentication algorithm between the two now
- ◆ this algorithm has problems (MITM and Replay)
  - also single point of failure
  - shared symmetric secrets outside a domain?
- ◆ a family of improvements include
  - Needham-Schroder (78)
- ◆ Kerberos v4 and v5

# asymmetric or public-key crypto

---

- ◆ key generation produces (public, private) key pairs
- ◆ can give Public key away, secure private key (somehow ... and hard ...)
- ◆ two important services:
  - **signature** - append bit string that proves you signed a message, uses private key (authenticate)
  - **confidentiality** - uses public key (encrypt)

# algorithms include:

---

- ◆ RSA - company and algorithm
  - invented by Rivest, Shamir, Adleman
  - key lengths, e.g., 512/1024 or inbetween
  - block size is smaller than key length
  - output will be length of key
- ◆ DSS - US govt. competition for RSA
- ◆ Diffie - Hellman (older than RSA)
  - doesn't allow signatures/encryption

# signatures

---

- ◆ can “sign” a message
- ◆  $\text{sign}(M, \text{private key})$ 
  - but actually
  - use Media Digest algorithm to compute hash
  - say MD5  $\rightarrow$  128 bits (hash(M)  $\rightarrow$  bit string)
  - then run private key over bit string to get signature
  - send (Msg, signature) to receiver
- ◆ receiver uses sender public key to verify

# confidentiality

---

- ◆ you send me secure email
- ◆ obtain my public key SOMEHOW
- ◆  $\text{encrypt}(\text{Msg}, \text{public}) \rightarrow \text{encrypted message}$
- ◆ OK, the message has to be ASCII ...
- ◆ I decrypt with my private key
- ◆ ? how did you get my public key
- ◆ ? what if Joe spoofed me with his public key and you sent him a msg for me

# big news (well maybe not)

---

- ◆ public, private keys are cybercrud
- ◆ one must make sure public key is somehow truly associated with party X
- ◆ and not party Y spoofing party X
- ◆ known as “man in the middle” attack if that happens
- ◆ various schemes exist for acquiring public keys (ssh/ssl/pgp, including “certificates”)

## so note four operations

---

- ◆ **sign** (mac hash) with SELF private key
- ◆ **verify** (mac hash) with OTHER public key
- ◆ **encrypt** with SELF | OTHER public key
- ◆ **decrypt** with SELF private key
  - definitely not OTHER, else bad news
- ◆ RSA can do all 4. DSS can do sign/verify

# Certificate Authorities

---

- ◆ it is presumed that one way to solve the problem of public key distribution
- ◆ is to get a signed public key from a trusted 3rd party
- ◆ call that node a CA - certificate authority
- ◆ nodes need the CA's public key to start with
- ◆ can verify “certificate” signed by CA
- ◆ certificate = Joe Bob's public key, CA sig

# certificate then roughly

---

- ◆ your public key
- ◆ your name
- ◆ a possible timestamp (it expires at some point)
- ◆ signature over all of the above
- ◆ you need signer's public key to verify
  - who signed signer's certificate ?

## certs, cont.

---

- ◆ certificate can be stored anywhere
  - only CA can generate them
- ◆ CA doesn't have to be accessible
  - but would be if network database of course
- ◆ so why don't we have CAs ?
  - netscape supports certificates and there are a few (verisign)
  - “cross-certification” as opposed to hierarchical cert. may not be possible in some cases

# X509 certificate

---

- ◆ version
- ◆ serialNumber - with CA's name, id's cert.
- ◆ signature - (not the signature), names algorithm used to compute signature
- ◆ issuer - name of CA
- ◆ validity - how long it lasts
- ◆ subject - name of user

## X 509 cont.

---

- ◆ subjectPublicKeyInfo - contains algorithm identifier AND public key
- ◆ ETC.
- ◆ encrypted - (the signature)

# certificate formats - > 1 kind

---

- ◆ a few kinds out there at the moment
- ◆ X509 (e.g., netscape/web)
  - may be quite large
- ◆ RSA may be available in DNS
  - call ‘em DNS certificates
  - sign user name/IP/DNS names
- ◆ PGP has its own kind

## bottom line:

---

- ◆ a certificate is basically a signed public key
- ◆ (public key, name, timestamp, signature)
- ◆ what good are they?
- ◆ authentication mechanism
- ◆ if widely deployed, could replace passwords
- ◆ ask how they are stored?
  - if stored on computer, and computer crashes ...?
  - and where is your private key stored too?

# principles of authentication

---

- ◆ something you know
  - a password/passphrase/PIN number
  - “abracadabra”
- ◆ something you have
  - an object, a VISA card, a “dongle”, a smart card, a physical key
- ◆ something you are
  - your fingerprint/retina pattern
- ◆ combining these usually improves security
  - Pin # and VISA card

# passwords - words while passing thru

---

- ◆ password mechanisms include:
- ◆ 1. passwords used as authentication;
  - e.g., with DES on UNIX (prove you know shared-secret)
- ◆ 2. authentication done as plaintext over network
  - telnet/ftp/pop/http basic authentication
- ◆ 3. advanced password algorithms:
  - one time password or variations on that theme
  - challenge-response with a
  - hw token (counter or timestamp)

# passwords

---

- ◆ classic password algorithm:
  - type in a string (blank the screen)
  - convert the string via DES/MD algorithm to a hash
  - compare the hash to a saved hash in a file
  - better: hash a fixed known thing that is somehow unique to user (userid ...)
  - this helps rule out on-line brute force comparison that can match  $> 1$  user in a password file

# password problems

---

- ◆ the password is weak
  - force the user to type in a stronger password
- ◆ the user writes the password down
  - on a card and then launders it!
  - or puts it on a yellow stickee on his monitor
- ◆ dictionary attacks on passwords
- ◆ brute-force attacks because password file is easily available
  - exploit gets it or multi-user system makes it easy to get to

# password problems cont.

---

- ◆ variation on weakness
  - the password set of characters is too limited
  - too short
    - » uppercase only
    - » a 4-digit PIN number
  - mathematically not terribly random
    - » 256-bit space with ASCII means you lost half your space (7 out of 8 bits)
- ◆ a random # is best, expressed in hex

# password attacks, cont.

---

- ◆ someone sees you type it in
  - PIN number in a public place ...
  - of course, in that case, there are 2 authentication mechanisms
- ◆ if attacker can obtain password file
  - they can take their time guessing to see if they can match Alice/Bob/other users hash
  - off-line attack
  - sometimes on-line attack may be done
  - this is why you get 4 tries and then the bank machine eats your card (or login slows down)

# password meta-problems

---

- ◆ user has many passwords
  - different for every computer
  - hard to remember
- ◆ which is why security is:
  - usually not helpful in terms of “ease of use”
  - consider the W98 “hit ESC to get around the password”
- ◆ not a good system in several variations
  - they make you change your password every 30 days
  - you vary between “hi” and “there”
  - what is your Mother’s Maiden Name?

# password meta-problems

---

- ◆ ARE THERE BETTER SCHEMES?
  - yes, but they are uncommon
  - combine  $> 1$  of the basic authentication ideas
  - one-time passwords/hardware tokens
  - why certificates are better, aren't they?

# password case #1 - ssh guessing

---

- ◆ password-based protocols suffer from RANDOM machine-based distributed password guessing attacks.
- ◆ ssh/windows login (fileshare)/sql login
  - probably not telnet so much anymore ... (still there though)
- ◆ what are e.g., ssh counter-measures?
- ◆ what are botnets doing about it?

# trust relationships are

---

- ◆ **fundamental to distributed secure systems**
- ◆ understand the trust relationship 1st
- ◆ then design the system
- ◆ **risk alleviation** systems may be able to takeover when trust relationships are too hard
  - bank card is stolen - only out \$50
- ◆ trust relationships consist of
  - us (or us1 plus us2) versus them
- ◆ e.g., every computer cannot trust every other computer on the Internet by definition
- ◆ interior lines are important

# study questions

---

- ◆ given an encryption algorithm like DES, could you design a key establishment protocol that computes a new shared secret between Alice and Bob?
- ◆ how do you protect a private-key on-line, on a multi-user o.s.?
- ◆ what issues can you think of with storing keys on a computer?
- ◆ cryptanalysis is made easier by doing what? where possible.

# one more question:

---

- ◆ your bank has just deployed a new wonderful eye-ball scan authentication technique
  - scan eyeball and store in computer file like so:
    - » (name, eyeball-scan-bits)
  - user at ATM has eye-ball scanned, compared with bits on computer over network to authenticate
- ◆ how many ways can you think of to attack this system?
- ◆ what problem previously mentioned does this sound like? is it the same problem?

# modest homework request

---

- ◆ get a partner in class
- ◆ exchange email addresses
- ◆ install GNUPG (pgp in modern guise)
- ◆ now send each other a SEKRAT MESSAGE
  - that is signed
  - and encrypted
- ◆ be the 1st on the block to become a GNUPG user
