Abstract

This paper discusses an approach to decomposition of multi-valued functions and relations into networks of two-input gates implementing multi-valued MIN and MAX operations. The algorithm exploits internal flexibilities generated in the process of decomposition as well as of the incompleteness of the initial specification. Experimental results over a set of multi-valued benchmarks show that this approach outperforms other approaches \cite{5,6} in the quality of final results and CPU time.

Introduction

Decomposition of multi-valued relations has important applications in data mining and machine learning \cite{1}. Potentially, multi-valued decomposition can be also used in the design of multi-valued hardware devices, software compilers, and asynchronous logic synthesis \cite{2}.

Several approaches to multi-valued functional decomposition have been proposed \cite{3-7}. Applicability of \cite{3} is limited to relatively simple multi-valued objects due to the use of explicit data structures. Approaches \cite{3,4} rely on Multi-Valued Decision Diagrams (MDDs), which have been shown to be less robust than other representations \cite{8}. MDD-based approach used in \cite{5,6,7} does not allow for variable reordering, which significantly improves the performance of multi-valued computation.

Our approach to MV decomposition is based on

- Binary-Encoded Multi-Valued Decision Diagrams
  BEMDDs have been introduced in \cite{8} to solve the problem of support minimization for multi-valued relations. This hybrid data structure combines the efficiency of BDDs \cite{9} for implicit representation with the expressive power of MDDs \cite{6} for manipulation of MV relations.

- Bi-Decomposition
  This concept has been under development for the last decade \cite{10}. Recently, it has been successfully applied to Boolean functions \cite{11}.

Essentially, bi-decomposition consists in recursive splitting of large logic blocks into compositions of the three smaller logic blocks interconnected as shown in Fig. 1. Blocks A and B typically have reduced complexity (expressed in terms of smaller support or more don’t-cares) compared to the initial logic block. Block C always has two inputs. In the binary case, block C is an elementary Boolean function, while in the multi-valued case, it is a MAX or MIN gate.

The following sections present our approach.

Section 1 introduces BEMDDs as a vehicle for manipulation of multi-valued relations. Section 2 introduces operations on MV relations. Section 3 lists conditions for the existence of MAX- and MIN-bi-decomposition and formulas to derive relations of blocks A and B. Section 4 outlines the main bi-decomposition algorithm. Section 5 gives experimental results. Section 6 concludes the paper.

1 BEMDDs

As stated in the introduction, we advocate the use of BEMDDs as the representation of choice for multi-valued relations. The motivation is that BEMDDs are efficient for large functions and lead to improved decomposition procedures compared to other representations: multi-valued cubes and cube partitions \cite{3}, edge-valued BDDs and classical MDDs \cite{6,7}.

In BEMDDs, multi-valued variables are encoded using the smallest sets of binary variables. A k-valued variable requires at least \(\lceil \log_2(k) \rceil\) binary variables to uniquely encode its values. (Here the vertical bars stand for the closest larger integer.)

For example, a 5-valued variable A is encoded using the set of three binary variables \{a_1, a_2, a_3\}. In the simplest case, the set of all possible values of variable A, \{0, 1, 2, 3, 4\}, is encoded using the set of binary cubes:

\{ a_\bar{a}_1\bar{a}_2\bar{a}_3, a_1a_2a_3, a_1\bar{a}_2a_3, a_1a_2a_3, a_1a_2a_3 \}.

If k is not an integer power of two, the minimum length binary encoding results in \(2^{\lceil \log_2(k) \rceil} - k\) spare minterms. It is possible to leave them unused and account for them in the decomposition routines. In this case, it is necessary to remember that the domain of binary variables encoding the inputs is limited to only those minterms that provide codes for the values of multi-valued variables. Experimentally, we found that this approach increases the BEMDD size and makes traversal routines more complicated.
From the practical point of view, it is better to distribute the unused minterms between the values of the function. For example, consider the two encodings of ten values using sixteen minterms of the four binary variables shown in Fig. 2.

\[
\begin{array}{cccccc}
00 & 0 & 4 & 8 & 8 & 00 & 0 & 2 & 7 & 4 \\
01 & 1 & 5 & 9 & 9 & 01 & 0 & 2 & 8 & 4 \\
11 & 3 & 7 & 10 & 10 & 11 & 1 & 3 & 10 & 6 \\
10 & 2 & 6 & 10 & 10 & 10 & 1 & 3 & 9 & 5 \\
\end{array}
\]

\[BVA \quad 0 \quad 1\]

Fig. 2. Two ways to encode ten input values using binary variables and v2 as follows:

\[R(a,b_1,b_2,v_1,v_2) = a\bar{b}_2b'_2 + a\bar{b}_1b_2v_1v_2 + a\bar{b}_1(v_2+v_1) + \bar{a}b_1b_2v_1' + a\bar{b}_1b_2 + ab_1v_1'.\]

Each of the six terms in the above formula is obtained directly by encoding a cell of the multi-valued Karnaugh map in Fig. 3. The Karnaugh map and the BEMDD for the resulting binary relation R are shown in Figs. 4 and 5.

\[
\begin{array}{cccccc}
00 & 01 & 11 & 10 & 00 & 01 & 11 & 10 \\
01 & 01 & 01 & 01 & 01 & 01 & 01 & 01 \\
11 & 11 & 11 & 11 & 11 & 11 & 11 & 11 \\
10 & 10 & 10 & 10 & 10 & 10 & 10 & 10 \\
\end{array}
\]

Fig. 4. The Karnaugh map for the binary relation encoding multi-valued relation R(A,B).

2 Operations on MV Relations

This section introduces important theoretical concepts and operations used in the procedures that check the existence of MAX- and MIN-bi-decomposition and derive the multi-valued relations for the logic blocks A and B.

Interval Relation

The bi-decomposition algorithm discussed in this paper is applicable to multi-valued relations satisfying the property of a function interval \([5]\). Below this definition is restated with some adaptation to the terminology accepted in this paper.

Definition. A multi-valued relation is an interval relation if in each vertex (minterm) of the domain, the output values form a contiguous range.

For example, relation R(A,B) in Fig. 3 is an interval relation, but if, for example, in the vertex (0,0) instead of value set \{0,1,2\} it had value set \{0,2\}, it would not be an interval relation because values 0 and 2 do not form a contiguous range.

From the practical point of view, limiting our attention to only interval relations does not seem to restrict the applicability of the decomposition method because the majority of multi-valued benchmarks satisfy this property. For those that do not satisfy, below we propose a simple way to convert a non-interval multi-valued relation to an interval one, by filling in the unused values between the smallest and the largest values used in each vertex.

Lower and Upper Bound Intervals

Definition. For the given multi-valued relation R, a lower (upper) bound interval (denoted R_LBI and R_UBI) are multi-valued relations depending on the same input variables, having the same number of possible output values, and differing only in sets of the output values. In each vertex of the domain, the LBI takes all the
values starting from 0 up to (and including) the first value used in this vertex by the given relation, while the UBI takes all the values starting from (and including) the largest value used by the given relation up to the largest possible value of the output variable.

Fig. 6 illustrates this definition. An interval relation \( F \) is shown on the left. Its LBI and UBI are given in the center and on the right. For example, consider vertex (0,2). The LBI in this vertex has values starting from 0 up to the first value used by \( F \), which is 1. The UBI in this vertex has all the values starting from the last value of \( F \), which is 2, up to the largest possible value of the relation, which is also 2.

<table>
<thead>
<tr>
<th>( F )</th>
<th>( F_{\text{LBI}} )</th>
<th>( F_{\text{UBI}} )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( V )</td>
<td>( 0 )</td>
<td>( 1 )</td>
</tr>
<tr>
<td>( 1 )</td>
<td>( 0 )</td>
<td>( 0 )</td>
</tr>
<tr>
<td>( 2 )</td>
<td>( 1 )</td>
<td>( 0 )</td>
</tr>
</tbody>
</table>

Fig. 6. Example illustrating the upper and lower bound intervals.

If the relation \( R(x,v) \) is represented by a BEMDD over the input-encoding variables \( x \) and the value-encoding variables \( v \), computation of its lower (upper) bound interval can be performed using the formulas:

\[
R_{\text{LBI}}(x,v) = \exists v \left[ R(x,v) \text{ and } R_{v<w}(v,w) \right]_{w:=v},
\]

\[
R_{\text{UBI}}(x,v) = \exists v \left[ R(x,v) \text{ and } R_{v>w}(v,w) \right]_{w:=v},
\]

where \( \exists \) stands for the existential quantification and \( R_{v<w} \) and \( R_{v>w} \) are characteristic functions of relations “more than” and “less than” which depend on two equal-sized interleaved sets \( v \) and \( w \) of value-encoding variables.

The first formula is interpreted as follows. For each vertex of the domain (given by one assignment of variables \( x \)), the lower bound interval contains all values \( w \) (\( v \) after variable replacement), for which there does not exist value \( v \) belonging to the relation such that \( v < w \).

The interpretation of the second formula is similar.

It is interesting to note that if the initial relation is not an interval relation, its LBI and UBI are the same as the LBI and UBI of the interval relation created by filling in the intermediate unused values. Therefore, if the relation is represented by the LBI/UBI pair, there is no need for a specialized procedure to convert non-interval relations into interval ones!

In the procedures below, multi-valued relations are represented as LBI/UBI pairs. This simplifies processing because relations of blocks A and B resulting from the bi-decomposition are also computed as LBI/UBI pairs. In our experiments, we observed an additional advantage of this representation, namely that the BEMDDs for LBI/UBI are typically smaller than those for the pure lower/upper bounds as defined in [5].

**Interval Increments and Decrements**

Another operation for the manipulation of interval relations is the interval increment and decrement discussed in this subsection.

**Definition.** For the given multi-valued interval relation \( R \), the upper increment (decrement) (denoted \( R^{\text{UI}} \) and \( R^{\text{DI}} \)) are multi-valued relations depending on the same input variables, having the same number of possible output values, and differing only in sets of the output values. In each vertex of the domain, the value set of \( R^{\text{UI}} \) (\( R^{\text{DI}} \)) is determined as the value set of the given relation plus (minus) one value at the upper end of the value set.

Similarly, it is possible to define the lower increment (decrement) of an interval relation by adding (subtracting) one value at the lower end of the value set.

Fig. 7 illustrates the definition for the upper increment and decrement. An interval relation \( R \) is shown on the left. \( R^{\text{UI}} \) and \( R^{\text{DI}} \) are shown in the center and on the right. For example, consider vertex (1,1) with value set \{0,1,2\}. \( R^{\text{UI}} \) in this vertex has values \{0,1,2\} created as the same value set plus the value immediately following the largest value, which is 2. \( R^{\text{DI}} \) in this vertex has value set \{0\} created as the same value set as \( R \) minus the largest possible value in the set, which is 1. The dashes in the table for \( R^{\text{UI}} \) mean that the value set for some vertices is empty.

<table>
<thead>
<tr>
<th>( R )</th>
<th>( R^{\text{UI}} )</th>
<th>( R^{\text{DI}} )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( V )</td>
<td>( 0 )</td>
<td>( 1 )</td>
</tr>
<tr>
<td>( 1 )</td>
<td>( 0 )</td>
<td>( 1 )</td>
</tr>
<tr>
<td>( 2 )</td>
<td>( 0 )</td>
<td>( 1 )</td>
</tr>
</tbody>
</table>

Fig. 7. Example illustrating the lower increment and decrement of the interval relation \( R(A,B) \).

The upper (lower) increment (decrement) can be computed using the BEMDD representation as follows:

\[
R^{\text{UI}}(x,v) = \exists v \left[ R(x,v) \text{ and } R_{v<w}(v,w) \right]_{w:=v},
\]

\[
R^{\text{DI}}(x,v) = \exists v \left[ R(x,v) \text{ and } R_{v>w}(v,w) \right]_{w:=v},
\]

where \( \exists \) represents the existential quantification and \( R_{v<w} \) and \( R_{v>w} \) are characteristic functions of relations “more than” and “less than” which depend on two equal-sized interleaved sets \( v \) and \( w \) of value-encoding variables.

The underlying BDD package does not support the complement edges, the formulas with the universal quantifier are likely to be more efficient because they do not require complementation of the intermediate result.

**3 Checking and Deriving Bi-Decomposition**

This section presents the main contribution of this paper: the formulas for checking the existence of strong (weak) MAX- and MIN-bi-decomposition and deriving the resulting relations for blocks A and B. It is only necessary to consider the case of MAX-bi-decomposition because the case of MIN-bi-decomposition can be checked (derived) using the same formulas after swapping \( R_{\text{LBI}} \) and \( R_{\text{UBI}} \).

**Definition.** Expression \( R_{\text{crit}}(x,v) = [R_{\text{LBI}}(x,v)]^{\text{UI}} \) is called critical relation. For each vertex of the domain, the critical relation contains all the values situated below the allowed set of values of the relation \( R(x,v) \).

**Theorem 1.** Multi-valued interval relation \( R(x,v) \) specified by UBI \( R_{\text{UBI}}(x,v) \) and LBI \( R_{\text{LBI}}(x,v) \) has strong MAX-bi-decomposition with variable sets \( (x_a,x_b) \) iff

\[
R_{\text{crit}}(x,v) \& \exists_{x_a} R_{\text{UBI}}(x_a,v) \& \exists_{x_b} R_{\text{LBI}}(x,v) = 0.
\]

**Sketch of the proof.** For each vertex of the domain, the lower bound interval \( R_{\text{LBI}}(x_a,v) \) contains all the values below the value
Each of the two components with the existential quantifier computes the projection of the upper bound interval in the direction of variables $x_a$ and $x_b$. The product of projections computes the projection of the upper bound interval in the direction of variables $x_a$ and $x_b$. The product of projections computes the projection of the upper bound interval in the direction of variables $x_a$ and $x_b$.

![Formula](image)

**Theorem 2.** Multi-valued relation $R(x,v)$ specified by its UBI $R_{\text{UBI}}(x,v)$ and LBI $R_{\text{LBI}}(x,v)$ is MAX-bi-decomposable in the weak sense with the variable sets $(x_a, x_b)$ iff $
abla(x) = \exists x_a R_{\text{UBI}}(x,v) \land \exists x_b R_{\text{LBI}}(x,v) \land \exists x_a R_{\text{UBI}}(x,v) \land \exists x_b R_{\text{LBI}}(x,v) \neq 0$.

**Proof.** The weak MAX-bi-decomposition exists if, after excluding variables $x_a$ from the support of block $B$, the UBI of this block $(\exists x_b R_{\text{UBI}}(x,v))$ has no overlap with the critical relation in at least one vertex of the domain where the value set of the critical relation is not empty, Q.E.D.

The quality of weak MAX-bi-decomposition with one variable in $x_a$ can be measured by the number of minterms of the Boolean function $\exists x \psi(x)$. 

**Theorem 3.** If the multi-valued relation $R(x,v)$ specified by UBI $R_{\text{UBI}}(x,v)$ and LBI $R_{\text{LBI}}(x,v)$ is MAX-bi-decomposable with the variable sets $(x_a, x_b)$, the relations of blocks $A$ and $B$ are:

- $R^A_{\text{LBI}} = \exists x_b \{v = 0\} + R^B_{\text{LBI}} + \exists v (R^A_{\text{UBI}} \land \exists x_b R^B_{\text{UBI}})$.
- $R^A_{\text{UBI}} = \exists x_b R^B_{\text{UBI}}$.
- $R^B_{\text{LBI}} = \exists x_a \{v = 0\} + R^A_{\text{LBI}} + \exists v (R^B_{\text{UBI}} \land \exists x_a R^A_{\text{UBI}})$.
- $R^B_{\text{UBI}} = \exists x_a R^A_{\text{UBI}}$.

**Proof.** Deriving the UBIs for both blocks is straightforward. Computation of the LBI for block $A$ is based on the observation that should contain zero value ($v = 0$) everywhere, except those vertices of the domain where the critical relation ($R_{\text{crit}}$) overlaps with the projection of the UBI $(\exists x_b R_{\text{UBI}}(x,v))$. In the latter cases, to prevent the violation of the initial relation, the LBI of block $A$ should be set to the LBI of the initial relation.

In the formulas for block $B$, the projection of the UBI is replaced by the completely-specified multi-valued function of the block $A$, found after bi-decomposition is performed recursively for its fanins, Q.E.D.

The formulas for deriving the relations for blocks $A$ and $B$ are also true for the case of weak bi-decomposition if set $x_b$ is assumed to be empty (no quantification w.r.t. $x_b$).

The example in Fig. 8 illustrates Theorem 3.

![Table](image)

**Fig. 7.** Example of checking the existence of strong MAX-bi-decomposition for relation $R(A,B)$.

**Fig. 8.** Example illustrating the computation of multi-valued relations for blocks $A$ and $B.$

### 4 Bi-Decomposition Algorithm

This section presents the upper-level procedure that performs one step of recursive bi-decomposition (Fig. 9).

Procedure BiDecompose() is called with the LBI/UBI pair representing a MV relation. It returns a completely-specified MV function implemented by the decomposed network of blocks.

If the relation has inessential variables, they are removed using a simple greedy algorithm.

Support size, $|S|$, is checked for being less than two. If the support size is $0$ (or $1$), a block representing a constant (or multi-valued literal) is added to the network. Otherwise, the procedure GroupVariables() is called to find sets $X_A$ and $X_B$, leading to a bi-decomposition with MAX and MIN gates.
Procedure FindBestVariableGrouping() considers the variable sets and determines the best one. The cost function evaluating the variable sets takes into account two factors: how many variables are included into $X_A$ and $X_B$ (the more, the better), and whether $X_A$ and $X_B$ are well-balanced (the closer their sizes are, the better). The procedure returns the best variable grouping and the indication what decomposition to perform (MAX or MIN).

```
procedure BiDecompose (bdd LBI, bdd UBI)
{  bdd LBA, UBA, LBIb, UBIb, S, Fa, Fb, F;
  if ($|S| < 2$) {
    (F, gate) = CreateConstantBlockOrLiteral (LBI, UBI);
    AddBlockToDecompositionTree (F, gate);
    return F;
  }
  bdd $X_A^{OR}$, $X_B^{OR}$, $X_A^{AND}$, $X_B^{AND}$, $X_A^{BEST}$, $X_B^{BEST}$;
  ($X_A^{OR}$, $X_B^{OR}$) = GroupVariablesOR (LBI, UBI);
  ($X_A^{AND}$, $X_B^{AND}$) = GroupVariablesAND (LBI, UBI);
  ($X_A^{BEST}$, $X_B^{BEST}$, gate) = FindBestVariableGrouping ($X_A^{OR}$, $X_B^{OR}$, $X_A^{AND}$, $X_B^{AND}$);
  if ($X_A^{BEST}$, $X_B^{BEST}$) == ($\emptyset$, $\emptyset$) 
    return CompletelySpecifiedFunction (LBI, UBI);
  (LBIa, UBIa) = DeriveBlockA (LBI, UBI, $X_A^{BEST}$, $X_B^{BEST}$, gate);
  F_B = BiDecompose (LBIa, UBIa);
  (LBIb, UBIb) = DeriveBlockB (LBI, UBI, F_B, $X_A^{BEST}$, $X_B^{BEST}$, gate);
  F_B = BiDecompose (LBIb, UBIb);
  F = Gate (Fa, Fb);
  AddBlockToDecompositionTree (F, gate);
  return F;
}
```

Fig. 9. The pseudo-code of bi-decomposition algorithm.

If variable grouping with non-empty variable sets $X_A$ and $X_B$ is not found, procedure GroupVariablesWeak() finds the best variable grouping for the weak MAX- or MIN-bi-decomposition. If there is no weak decomposition, a completely specified function from the interval (LBI, UBI) is returned. In practice, it happens in less than 10% of cases, and the non-decomposable gate rarely has more than 2 inputs. An example if a weakly-non-decomposable gate is an Exclusive-OR for relations with binary inputs/outputs.

Given the variable sets and the type of decomposition, the LBI/UBI pair for block A are derived using formulas of Section 3. Next, procedure BiDecompose() is called recursively for block A, returning the completely specified function $F_A$ representing one part of the netlist. $F_A$ together with variable sets $X_A$ and $X_B$ is used to compute the LBI/UBI pair of block B. Procedure BiDecompose() is called again for block B.

Finally, multi-valued functions $F_A$ and $F_B$ derived in the process of decomposition and the information about the gate, is used to find the function $F$ implementing the initial relation.

Similar to the case of bi-decomposition for Boolean functions [11], we implemented cache to store the functions represented by the decomposed parts of the network. However, savings due to the component reuse, which were substantial in the binary case, were negligible for MV relations (less than 1% of gates). One of the reasons for this is that there are many different MV literals.

5 Experimental Results

We implemented the bi-decomposition algorithm in a C++ program BI-DECOMP-MV with the BDD package BuDDy [12]. We tested our program on a 933MHz Pentium III PC under Windows 2000 using multi-valued machine-learning and data-mining benchmarks available from Portland Logic Optimization Group (POLO) [13].

Experimental results are listed in Table 1. Column “Bmark” gives the benchmark name. “In/Out” is the number of inputs and outputs. “Val” is the sum total of input values. “Cubes” is the number of lines (MV cubes) in the input file. “BDD nodes” is the number of nodes in the shared ROBDD without complement edges representing the BEMDD for LBI and UBI before the bi-decomposition. “Reading time” is the time needed to read the input file and derive the BEMDD representation for the problem.

Column “Logic levels” gives the number of levels in the decomposed network. Multi-valued literals are counted as logic blocks. “DFC” gives the Decomposed Function Cardinality measured as the sum total of products of the input-variable cardinalities for all blocks including the multi-valued literals. The section “Gates” gives the number of MAX/MIN gates (“MM”), literals (“Lits”), non-decomposable blocks (“NonDec”) and the total number of gates in the decomposed network. Finally, the column “BiDec time” gives the runtime of bi-decomposition.

The results of bi-decomposition for all benchmark functions have been verified by a built-in verifier, which computed a completely-specified MV function representing the decomposed network and checked that it is contained in the interval given by the original relation.

Table 2 compared the experimental results produced by BI-DECOMP-MV with those of a multi-valued bi-decomposer YADE [5] based on similar principles. The runtime of BI-DECOMP-MV shows the advantage of BEMDDs for the manipulation of MV relations.

6 Conclusions

We presented a new approach to decompose MV relations into netlists of two-input MV MAX and MIN gates. The decomposition algorithm is based on BEMDDs and formulas with quantifiers evaluated using a standard BDD package. Our algorithm can be characterized as follows:

• The generated netlists are compact, because the algorithm exploits external and internal don’t-cares.

• The netlists are well-balanced (i.e., the subnetworks for both inputs of a logic gate are close in the number of gates), which reduces the delay of the resulting circuit.

• It can be shown that the resulting multi-valued netlists are 100% testable for single MV stuck-at faults. A test pattern generation technique can be integrated into the decomposition algorithm with little if any increase in the complexity and runtime.

The future work may include extending the algorithm to work with arbitrary standard cell libraries (not only MAX and MIN) and integration of ATPG into the process of decomposition.
